Report DSO-11-04

## Binding Agents in Embankment Dam Protective Filters

Dam Safety Technology Development Program

U.S. Department of the Interior  
Bureau of Reclamation  
Technical Service Center  
Denver, Colorado

March 2011

**REPORT DOCUMENTATION PAGE**

*Form Approved  
OMB No. 0704-0188*

The public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing the burden, to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to any penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number.

**PLEASE DO NOT RETURN YOUR FORM TO THE ABOVE ADDRESS.**

| <b>14. ABSTRACT</b><br>Granular filters are used in embankment dams to protect against soil that may erode through cracks in the embankment core. It is required that the filter material itself not be able to sustain a crack. Design recommendations exist to limit cohesive behavior of filters. However, based on the observation of cemented behavior of filter materials in the field, it became clear that requirements beyond the existing ones related to grain size and plasticity were needed. The goal of the present research is to evaluate a new index test method to quantify the cementation potential for candidate filter materials for use in embankment dams. This report describes a modified sand castle test method and apparatus, test results for 12 different materials, conclusions from the research, as well as recommendations for future study. |                    |                                   |                                   |                                                            |                                                                        |

## **Mission Statements**

The U.S. Department of the Interior protects America's natural resources and heritage, honors our cultures and tribal communities, and supplies the energy to power our future.

The mission of the Bureau of Reclamation is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public.

# 1.0 Introduction and Project Description

Granular filters are used in embankment dams to protect against soil that may erode through cracks in the embankment core. It is required that the filter material itself not be able to sustain a crack. Early consideration of this issue led to a requirement that filter material not contain more than five percent fines<sup>1</sup> and be non-plastic.<sup>2</sup> This requirement results in soils that are “cohesionless.” While the requirement does limit the potential for cohesive behavior, it is now known that other agents can result in a filter sustaining a crack. These agents, which are not detected by the earlier tests, are usually soluble minerals or other precipitates. In the Western U.S. it had been noticed that filter material that had passed the earlier tests would exhibit brittle or “crispy” behavior several days after being placed and compacted. Closer examination of this in-place material indicated that some form of cementation occurred. In one extreme example, filter material was undercut during a forensic investigation and water flowed through the overhanging material with no sand grains detaching. This indicated the cemented filter had gained a good deal of strength (cohesion). As illustrated on figure 1, similar behavior was observed in an undercut stockpile of recycled (crushed) concrete on the Denver Federal Center campus. Based on this observed behavior, it became clear that test procedures beyond the original grain size and plasticity tests were needed to ensure that filter material will perform as desired and not exhibit cementitious behavior.

Figure 1.—Undercut recycled concrete material exhibiting cemented (cohesive) behavior.

<sup>1</sup> Fines are soil particles that are finer than (i.e., which pass) the No. 200 sieve (75-micrometer opening size) as determined by ASTM D 6913.

<sup>2</sup> A non-plastic soil is a soil with a plasticity index equal to zero as determined by ASTM D 4318.

The goal of the present research is to evaluate a new index test method to quantify the cementation potential for candidate filter materials for use in embankment dams. Originally, a test known as the sand castle test was developed to measure this potential. The test was developed by P.R. Vaughan at the University of London in the 1970s (Vaughan 1978, Vaughan and Soares 1982) and involved submerging a compacted specimen, allowing it to collapse, and subsequently comparing the resulting “submerged” angle of repose (AOR) to the AOR in air. When materials collapse with a submerged AOR larger than the AOR in air, they are classified as cohesive and generally considered unsuitable for use as filter materials. However, the test is only loosely described in the literature. Compaction parameters are unclear, and precise criteria for evaluating the results are not established. Several other researchers, including some funded by the Bureau of Reclamation (Reclamation), have attempted to modify the sand castle test to make it more rigorous and to quantify how the results might be used to judge filter material quality (e.g., Yamaguchi 2001, Park 2003, Bolton et al. 2005).

It is suspected that the original sand castle test and the subsequent modified tests are not sensitive enough to distinguish small amounts of cementation potential. The results might lead to an unsuitable material being identified as suitable for filter applications. Of particular concern is that fact that cementation has not been given the opportunity to develop. It is likely that in the field a filter could be compacted in a moist condition and then allowed to dry in ambient air temperatures in excess of 100 °F (38 °C), especially in the Western U.S. These conditions are suspected to be favorable for development of cementation, and it is therefore desirable to develop an index test that takes these conditions into account. The following describes a modified sand castle test method and apparatus, test results for 12 different materials, conclusions from the research, as well as recommendations for future study.

## **2.0 Materials and Sample Preparation**

As shown in table 1, 12 materials were tested in this trial program. Several of the materials were commercially available ASTM C 33 concrete sands<sup>3</sup> (Index Nos. 36F-1138, 1139, 1140, 1141, 71Z-3, 4, 5, 6). Two other materials were pit run materials that required processing in order to meet the concrete sand gradation requirements (36F-1137, 71Z-2). One material consisted of recycled (crushed) concrete obtained from Denver Federal Center grounds (71Z-1), and another material consisted of a mixture of two different gradations of silica sand (36F-1136). These last two materials served as high and low cementation potential controls for the testing. All materials were processed (crushed, excess fines

---

<sup>3</sup> Since concrete sand is readily available and found to be acceptable in many filter applications, it was selected as the gradation for this study.

<sup>2</sup> Portions 10-20 and 20-40 silica sands combined to meet gradation requirement of C-33 sand.

<sup>3</sup> Excess coarse material removed to meet gradation requirements of C-33 sand.

<sup>4</sup> Excess fine material removed to meet gradation requirements of C-33 sand.

removed, etc.) as required (see table 1) to meet the gradation requirements set forth in ASTM C 33 for fine aggregate with the additional requirement of fines content of less than 2 percent before placement and 5 percent after placement (see Reclamation DS No. 13, Chapter 5, Protective Filters). None of the materials were washed to remove fines or other cementitious material. Gradations for each material, both as-received and as-tested, are provided in appendix A.

Each specimen was compacted to 100 percent relative density with a vibrating hammer according to ASTM D 7382 (see figure 2). This approach is preferred to impact (Proctor) compaction as it subjects the soil to less particle degradation and more closely mimics the way filter materials are compacted in the field (e.g., via vibratory rollers). The specimens were compacted in a saturated condition. A split mold was used, allowing for easier sample extraction. Once compacted, the specimens were immediately removed from the compaction mold and dried to constant mass in a 120 °F (49 °C) oven. Two to four specimens were prepared for each soil type depending on the amount of material available. Table 1 summarizes the characteristics of the 12 materials.

The sand equivalency value (SEV) was determined for each material according to ASTM D 2419 (as shown in table 1). The sand equivalency test is commonly used to assign an empirical value (SEV) to the relative amount, fineness, and character of claylike material present in the test specimen.

Figure 2.—Vibratory hammer compaction apparatus.

The individual test results are provided in appendix B. The SEV has been proposed by other researchers as a filter quality test (e.g., McCook 2005, Draft FEMA Filter Manual) and was investigated here to determine if it could be used as a predictive test. It is not anticipated that the SEV alone could be used to determine a filter material's suitability, but could be used along with other tests to those ends. It should be noted that, based on experience, manufacturer-provided SEVs are more favorable (i.e., higher) than those performed by independent laboratories.

### 3.0 Modified Sand Castle Test Apparatus and Procedure

An existing test apparatus was modified to accommodate the modified sand castle test. As shown on figure 3, an acrylic chamber with plumbing allowing the introduction of water from the bottom of the chamber was partially filled with gravel. This gravel served to evenly distribute the flow of water into the chamber and acted as a base for the specimens. Each specimen was placed on a perforated acrylic disc atop the gravel.

Figure 3.—Modified sand castle test apparatus.

Once the specimen was placed inside the chamber, water was introduced to a depth of 1 inch above the bottom of the specimen. The water level was maintained constant throughout testing. Specimens absorbed water via capillary action, and typical behavior involved the specimen crumbling from the bottom towards the top. The time required to reach several milestones was recorded, including the time required for (1) crumbling to progress to the water line (i.e., 1 inch up the specimen), (2) crumbling to progress to the mid-height of the specimen, (3) water to be absorbed to the top of the specimen, and (4) the specimen to completely collapse. In some cases, the specimen collapsed before it had crumbled to mid-height. Figure 4 presents photographs of some of these milestones.

## 4.0 Modified Sand Castle Test Results

The modified sand castle test was performed on all 12 materials (as summarized in table 2). The wide range of times observed indicates that the test is sensitive to cementation and holds promise as an index type test to indicate cementation potential for candidate filter materials. As anticipated, the two control materials, silica sand and recycled concrete, established the upper and lower bounds for 100 percent disintegration, respectively. At the time when the recycled concrete tests were stopped, very little to no crumbling had occurred – it is therefore inferred that it would have defined the upper bound.

Table 2.—Summary of results

| Index No. | Description/Source         | Average time to 100% disintegration (minutes) |
|-----------|----------------------------|-----------------------------------------------|
| 36F-1136  | CO Silica Sand             | 8.3                                           |

<sup>1</sup> Test terminated before collapse – material had shown no signs of disintegration after 3 weeks.

<sup>2</sup> Test terminated before collapse – material had reached 50 percent disintegration, but had not collapsed after more than 1 month.

Figure 4.—Test photographs illustrating typical behavior: profile view of (a) 50 percent disintegration, (b) 100 percent disintegration, and top view of (c) 100 % disintegration.

**Report DSO-11-04**  
**Binding Agents in Embankment Dam Protective Filters**

Several interesting trends were found in the results. First, figure 5 shows that there is a decreasing trend for time to 100 percent disintegration,  $T_{100}$ , with respect to SEV. It is likely that even a small deviation in the clay (or other mineral) content of any given sand could have a significant impact on the cementation potential. As discussed by Hurcomb (2001), clay particles can form “bridges” between larger sand particles, effectively binding them together. Only a small amount of clay is needed for this behavior to be observed. It should be noted that no discernable trend was observed between the percentages passing the No. 100 or No. 200 sieve and  $T_{100}$ . This is likely due to varying degrees of the “fines” (i.e., minus No. 200 sieve size particles) being composed of clay-size sand grains (i.e., rock flour) rather than true clayey type particles. For this reason, the SEV is a better indicator of cementation potential than the percent passing the No. 100 or No. 200 sieves.

Figure 5.—Variation of average time to 100 percent disintegration with SEV. (Note that the y-axis [time] is log scale.)

Further, the results indicate that there is some degree of correlation between  $T_{100}$  and the gradation of the filter material. Figures 6a and 6b show the variation of  $T_{100}$  with the coefficient of uniformity ( $C_u$ ) and the fineness modulus (FM), respectively. A weak increasing trend can be observed for both characteristics of the gradation. The results indicate that, in general, a more well-graded material has a higher potential to cement. This is likely due to the increased amount of grain-to-grain contact area and is in accordance with classic concrete design theory – the lowest cement content for a given strength comes from well-graded aggregates.

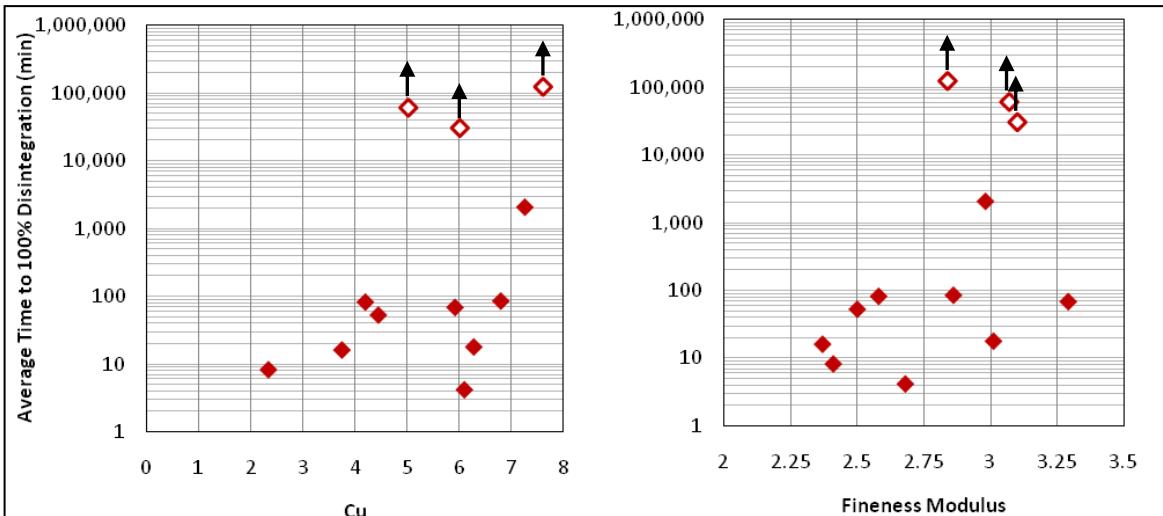

Figure 6.—Variation of average time to 100 percent disintegration with (a)  $C_u$  and (b) FM. (Note that the y-axis [time] is log scale.)

## 5.0 Conclusions

The research has resulted in the following conclusions:

- The modified sand castle test shows promise as an indicator of cementation potential. With modification (discussed below) and further research, an index value indicating cementation potential for candidate filter materials could be developed.
- Increasing SEV tends to indicate decreased collapse time (i.e., decreased cementation potential). A small amount of clay or other minerals may contribute significantly to cementation (Hurcomb 2001). Given that the fines content of sand can be composed of both clay-type and clay-sized particles (i.e., rock flour), the sand equivalency test may be a better indicator of cementation potential than the gradations alone.

**Report DSO-11-04**  
**Binding Agents in Embankment Dam Protective Filters**

- It should be recognized that the geologic origin of the material and its location relative to the recent water table may be as important as gradation, if not more so. The gradation-based tests (e.g., percent fines, SEV,  $C_u$ , FM) are not influenced by geologic origin or nearness to the water table. The modified sand castle test, on the other hand, inherently includes effects due to the geologic origin and location of the material.
- Samples with SEV > 95 took less than 10 minutes to collapse, and samples with SEV > 80 took less than 100 minutes to collapse. The typical minimum required SEV for concrete sand is 70-80, and the FEMA Filter Manual (draft) recommends that, for filters, SEV be greater than 80. Based on the present findings, the SEV > 80 criterion seems appropriate. However, the modified sand castle test is relatively inexpensive and should be run in conjunction with the sand equivalency test.
- Increasing  $C_u$  and FM tend to lead to increased collapse time. More well-graded sands tend to show increased ability to cement.
- Recycled (crushed) concrete should never be used as a filter material.
- It is not anticipated that either the modified sand castle test or the SEV test would ever be used alone to differentiate between suitable and non-suitable filter materials. Based on the results of the research described here, these tests do show merit as additional tools to help evaluate potential filter materials.

## **6.0 Future Research**

In moving towards a standardized index for cementation potential, future research should include the following:

- Several improvements to the current test method should be investigated. First, the test should be made more rapid. This could be accomplished by increasing the depth of water from 1 inch to 2 inches. Further, a surcharge load (e.g., 5-pound disc) could be placed on top of the specimen to mimic the stress state of an in-place filter.
- The effect of cure time (both in the oven and before being placed in the oven) should be investigated. If the binding agents are primarily mineral salts, the cure time likely does not matter; however, if the binding is due to pozzolanic action, the cure time may be an important parameter.

- The effect of geologic origin should be examined (e.g., alluvium from below a recent water table should be compared with alluvium from above any recent water table and crushed bedrock). These results could have a significant effect on the ability of a correlation based on gradation to predict filter performance.
- Once a final test method has been established, the repeatability of the method should be verified for a range of soils.
- After the repeatability has been verified, a range of soils should be investigated to determine an appropriate index system (i.e., range and increment).
- It may also be of interest to investigate the variation of cementation within the range of relative densities that Reclamation specifies for typical filter installations. The testing here was performed at 100 percent relative density per ASTM D 7382.
- The unconfined compressive strength should be determined on specimens after curing.

**Material Description**

Material from borrow area used to supply 1980 repair crushed in-house to meet requirements of C-33 sand

**Atterberg Limits**

PL= NP      LL= NV      PI= NP

**Coefficients**

D<sub>90</sub>= 2.1965      D<sub>85</sub>= 1.8766      D<sub>60</sub>= 0.9975  
D<sub>50</sub>= 0.7632      D<sub>30</sub>= 0.3960      D<sub>15</sub>= 0.2128  
D<sub>10</sub>= 0.1635      C<sub>u</sub>= 6.10      C<sub>c</sub>= 0.96

**Classification**

USCS= SP      AASHTO= A-1-b

**Remarks**

fines assumed to be non-plastic
